# **Problem Set 6**

published: 24 May 2023 discussion: 7 June 2023

#### Data Compression With And Without Deep Probabilistic Models

Prof. Robert Bamler, University of Tübingen

Course materials available at https://robamler.github.io/teaching/compress23/

**Note:** This problem set focuses entirely on the Asymmetric Numeral Systems (ANS) algorithm as there seemed to be quite a bit of confusion about this algorithm in the lecture. I decided to defer the promised exercise that uses range coding with our autoregressive machine-learning model of English text to a later problem set.

### **Problem 6.1: Positional Numeral Systems**

In the lecture, we introduced the Asymmetric Numeral Systems entropy coder as a generalization of positional numeral systems. Listing 1 on the next page shows our implementation of a class UniformCoder, which is an optimal entropy coder for a sequence of independent and uniformly distributed symbols by using a positional numeral system with a position-dependent base. The listing also contains a simple usage example.

- (a) **Correctness:** prove that **UniformCoder** is indeed a correct entropy coder, i.e., that decoding (i.e., pop) is the inverse of encoding (i.e., push):
  - (i) convince yourself that calling coder.push(symbol, base) and then calling coder.pop(base) returns symbol and restores the original state of coder, regardless of its original state (assuming that all method arguments are valid, i.e., base and symbol are integers with 0 < symbol < base);
  - (ii) convince yourself that setting symbol = coder.pop(base) with any positive integer base and then calling coder.push(symbol, base) restores the original state of coder, regardless of its original state (even if the coder was originally empty).
- (b) Compression performance: assume you use the UniformCoder to encode a sequence of symbols  $x_1, x_2, \ldots, x_k$  with respective bases (i.e., alphabet sizes)  $|\mathfrak{X}_1|, |\mathfrak{X}_2|, \ldots, |\mathfrak{X}_k|$ . Assuming the alphabet sizes are fixed, which sequence of symbols leads to the largest possible value of coder.compressed after encoding? What is this largest possible value and how long is its binary representation? Compare to the information content of the message assuming each  $x_i$  was drawn from a uniform distribution over the respective alphabet  $\mathfrak{X}_i = \{0, 1, \ldots, |\mathfrak{X}_i| 1\}$ .

```
class UniformCoder:
       def __init__(self, compressed=0):
           self.compressed = compressed
       def push(self, symbol, base): # Encodes a symbol \in \{0, ..., base - 1\}.
           self.compressed = self.compressed * base + symbol
       def pop(self, base):
                                         # Decodes a symbol \in \{0, \ldots, base - 1\}.
           symbol = self.compressed % base
           self.compressed //= base
                                         # ("//" denotes integer division.)
10
           return symbol
11
12
   # Usage example:
13
   coder = UniformCoder()
14
15
   coder.push(6, base=10)
16
   coder.push(13, base=16)
17
   coder.push(7, base=8)
18
   print(bin(coder.compressed))
                                      # Prints: "0b1101101111"
19
20
   print(coder.pop(base=8))
                               # Prints: "7"
21
   print(coder.pop(base=16)) # Prints:
                                          "13"
22
   print(coder.pop(base=10)) # Prints:
                                          "6"
```

Listing 1: A "stack"-like entropy coder that is optimal for uniformly distributed symbols.

## **Problem 6.2: Naive Asymmetric Numeral Systems**

Listing 2 shows the SlowAnsCoder from the lecture, which is a naive version of the Asymmetric Numeral Systems (ANS) algorithm (we will improve it in Problem 6.3).

- (a) **Correctness:** similar to Problem 6.1 (a), prove that **SlowAnsCoder** is a correct entropy coder, i.e., that decoding (i.e., pop) is the inverse of encoding (i.e., push):
  - (i) convince yourself that calling coder.push(symbol, m) followed by calling coder.pop(m) returns symbol and restores the original state of coder, regardless of its original state (assuming that all method arguments are valid, i.e., m is a list of nonnegative integers that sum to 2<sup>precision</sup> and 0 ≤ symbol < len(m) and m[symbol] ≠ 0; why is the last condition necessary?);</li>
  - (ii) convince yourself that setting symbol = coder.pop(m) (where m is again a list of nonnegative integers that sum to 2<sup>precision</sup>), followed by calling coder.push(symbol, m) restores the original state of coder, regardless of its original state (even if the coder was originally empty).

You may build your arguments on the fact that coder.uniform\_coder is a correct entropy coder, as you've shown in Problem 6.1 (a).

(b) Compression performance: in Problem 6.1 (b), you showed that a encoding (i.e., pushing) a symbol with a UniformCoder and some given base contributes  $\log_2(\text{base})$  bits to the amortized bit rate. Since pop inverts push, it therefore reduces the amortized bit rate by the same amount. Using these results, by how much does calling the method push on a SlowAnsCoder increase the amortized bit rate? Compare to the information content of the symbol under the approximate probability distribution  $Q(X_i = x_i) = \frac{m_i(x_i)}{n}$  where  $m_i(x_i)$  is m[symbol] in python.

#### **Problem 6.3: Streaming Asymmetric Numeral Systems**

While the SlowAnsCoder that we implemented in the lecture and discussed in Problem 6.2 above is a correct entropy coder with a very close to optimal bit rate, it has a problem: it is slow. More precisely, the runtime for encoding a single symbol with a SlowAnsCoder grows linearly with the amount of information content that has already been encoded onto the SlowAnsCoder before. Therefore, the runtime for encoding a sequence of k symbols scales quadratically in k, which makes this naive algorithm impractical for most common use cases. Let's fix this.

(a) Let's first understand exactly why the SlowAnsCoder from Listing 2 is slow. Figure 1 illustrates how compressed data accumulates as we encode a sequence of 10 symbols  $x_1, x_2, \ldots, x_{10}$  with a SlowAnsCoder. Different to, e.g., arithmetic coding or range coding, each new symbol that we encode conceptually pushes any previously encoded data to the left (i.e., towards more significant bits of

```
class SlowAnsCoder:
       def __init__(self, precision, compressed=0):
           self.n = 2**precision
                                      # ("**" denotes exponentiation.)
           self.uniform_coder = UniformCoder(compressed)
                                                              # See Listing 1.
       def push(self, symbol, m):
                                      # Encodes one symbol.
           z = self.uniform_coder.pop(base=m[symbol]) + sum(m[0:symbol])
           self.uniform_coder.push(z, base=self.n)
       def pop(self, m):
                                      # Decodes one symbol.
           z = self.uniform_coder.pop(base=self.n)
11
            # Find the unique symbol that satisfies z \in \mathfrak{Z}_i(symbol)
12
            # (using linear search just to simplify exposition):
13
           for symbol, m_symbol in enumerate(m):
14
                if z \ge m_symbol:
                    z -= m_symbol
                else:
17
                    break
18
           self.uniform_coder.push(z, base=m_symbol)
19
           return symbol
20
21
       def get_compressed(self):
22
           return self.uniform_coder.compressed
23
24
   # Usage example:
25
   precision = 4 # (for demonstration purpose only)
26
   m = [7, 6, 3]
27
   coder = SlowAnsCoder(precision)
28
29
   coder.push(0, m)
30
   coder.push(2, m)
31
   coder.push(1, m)
32
   print(bin(coder.get_compressed())) # Prints: "Ob101000"
33
34
   print(coder.pop(m)) # Prints: 1
35
   print(coder.pop(m)) # Prints: 2
   print(coder.pop(m)) # Prints: 0
```

Listing 2: A naive (slow) implementation of Asymmetric Numeral Systems (ANS).

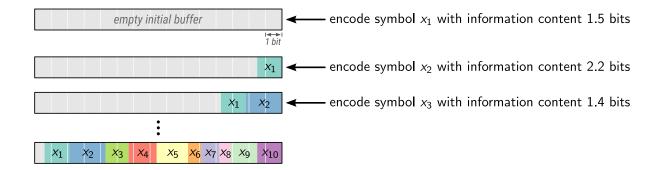

Figure 1: Stream coding with the naive SlowAnsCoder from Listing 2.

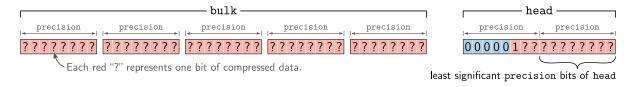

Figure 2: Representation of compressed data in streaming ANS with precision = 8.

coder.uniform\_coder.compressed). This operation becomes increasingly expensive with every additional symbol that we encode. Identify the lines of code in Listing 2 (and, more precisely, in Listing 1) that implement this increasingly expensive operation.

In order to speed up ANS and to make its runtime complexity linear in the length of the message, one uses the following trick (called "streaming ANS"): instead of representing the entire compressed data as a single (giant) integer, one splits the compressed data into a bulk part that holds most of the data in a dynamically sized array (aka "vector") and a head part with a fixed (and small) capacity. Figure 2 illustrates the simplest variant of this approach where each item of the vector bulk holds precision bits (referred to as "one word" of compressed data in the following), and head has a capacity of 2 words, i.e.,  $2 \times \text{precision}$  bits (thus, head can represent only integers from zero to  $2^{2 \times \text{precision}} - 1$ ).

Figure 3 illustrates what happens when we encode a sequence of symbols using such a streaming ANS coder. We use precision = 4 here for demonstration purpose. While the first 4 symbols fit into head in the example illustrated in Figure 3, encoding the fifth symbol  $x_5$  would lead to an overflow, i.e., it would lead to head  $\geq 2^{2 \times precision}$ , which is not allowed. Thus, before we encode  $x_5$ , we transfer the least significant precision bits of head to bulk, and we move the remaining part of head by precision bits to the right. Assuming a good vector implementation, transferring an integer number of bits from head to bulk requires only constant (amortized) runtime because even if there was already some data on bulk, we wouldn't need to move it around.

<sup>&</sup>lt;sup>1</sup>A more realistic value for real deployments would be precision  $\approx 32$ .

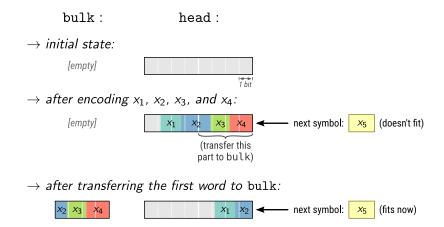

Figure 3: Stream coding with the StreamingAnsCoder (Listing 3) with precision = 4.

- (b) Continue Figure 3 until you have encoded 10 symbols  $x_1, \ldots, x_{10}$ . Assume that the symbols have the following information contents:
  - $x_1$  has information content 1.5 bits;
  - $x_2$  has information content 2.2 bits;
  - $x_3$  has information content 1.4 bits;
  - $x_4$  has information content 1.7 bits;
  - $x_5$  has information content 1.9 bits;
  - $x_6$  has information content 0.8 bits;
  - $x_7$  has information content 1.1 bits;
  - $x_8$  has information content 0.7 bits;
  - $x_9$  has information content 1.6 bits; and
  - $x_{10}$  has information content 1.5 bits.

You should find that some of the symbols get logically "split up" into two or even three not necessarily consecutive parts. Further, the first symbol  $x_1$  stays completely on head until the very end in this example.

In case you're curious, Listing 3 implements streaming ANS in Python. The main differences to our SlowAnsCoder class from Listing 2 are that (i) Listing 3 adds a potential transfer of one word from head to bulk to the beginning of the method pop as discussed above and, correspondingly, a potential transfer of one word from bulk to head to the end of the method push; and (ii) Listing 3 is self-contained as all calls to methods of UniformCoder were manually inlined.

```
class StreamingAnsCoder:
1
       def __init__(self, precision, compressed=[]):
2
           self.precision = precision
3
           self.mask = (1 << precision) - 1 # a string of precision 1-bits</pre>
4
           self.bulk = compressed.copy() # (We will mutate bulk below.)
5
           self.head = 0
           # Ensure that head is at least half filled unless bulk is empty.
           while len(self.bulk) != 0 and (self.head >> precision) == 0:
                self.head = (self.head << precision) | self.bulk.pop()</pre>
9
       def push(self, symbol, m):
                                          # Encodes one symbol.
11
            # Check if encoding onto head would lead to an overflow:
12
           if (self.head >> self.precision) >= m[symbol]:
13
                # Transfer one word of compressed data from head to bulk:
14
                self.bulk.append(self.head & self.mask) # (bitwise and)
15
                self.head >>= self.precision
16
                # This is the only point where head is (temporarily) less
17
                # than half filled despite bulk not being empty.
18
19
           # Below as in SlowAnsCoder (Listing 2), just with inlined calls:
20
           z = self.head % m[symbol]
21
           self.head //= m[symbol]
           self.head = (self.head << self.precision) | z # (This is</pre>
23
                # equivalent to "self.head * n + z", just slightly faster.)
24
25
       def pop(self, m):
                                          # Decodes one symbol.
26
           # Begin as in SlowAnsCoder (see Listing 2):
27
           z = self.head & self.mask # (same as "self.head % n" but faster)
28
           self.head >>= self.precision # (same as "//= n" but faster)
29
           for symbol, m_symbol in enumerate(m):
30
                if z \ge m_symbol:
31
                    z -= m\_symbol
32
33
                else:
                    break
34
           self.head = self.head * m_symbol + z
35
36
           # Detect whether push transferred data from head to bulk here:
           if (self.head >> self.precision) == 0 and len(self.bulk) != 0:
38
                # Transfer data back from bulk to head ("|" is bitwise or):
39
                self.head = (self.head << self.precision) | self.bulk.pop()</pre>
40
           return symbol
42
43
       def get_compressed(self):
44
           compressed = self.bulk.copy() # (We will mutate compressed below.)
45
           head = self.head
46
           # Chop head into precision-sized words and append to compressed:
47
           while head != 0:
                compressed.append(head & self.mask)
49
               head >>= self.precision
50
           return compressed
51
```

Listing 3: A complete streaming ANS entropy coder in Python. For a usage example, see lower part of Listing 2 (replace SlowAnsCoder with StreamingAnsCoder).
